**Betula pendula, Betula pubescens** and other birches in Europe: distribution, habitat, usage and threats

P. Beck, G. Caudullo, D. de Rigo, W. Tinner

Silver birch (*Betula pendula* Roth) and downy birch (*Betula pubescens* Ehrh.) are short-lived, relatively small broadleaved trees that occur throughout most of Europe, particularly in northern regions. In southern Europe, birch trees are confined to mountainous areas, as they do not tolerate prolonged summer drought. Birch has a light canopy of small serrated leaves, and characteristic smooth, white to grey bark. In northern regions, birch trees can dominate the landscape up to the tree-line, whereas in the centre of their range they often occur early in secondary succession because of their abundant seed production, low demands on soil quality, and intolerance of shade. Birch trees provide the predominant hard wood source in northern Europe, and some varieties of *Betula pendula* produce highly priced veneers, while *Betula pubescens* is mostly used for pulp and fire wood. Other rarer species of birch are endemic to Europe contributing to the continental biodiversity even at high elevations and latitudes.

*B. pendula* Roth is a medium-sized tree, growing up to 30m, while *B. pubescens* Ehrh. is relatively shorter, rarely growing beyond 20m and also less towards its northern range limits, up to dwarf trees in extreme habitats in the northern tundra and on mountains.* The bark of young trees is brown in colour, when mature it turns to silvery-white, with horizontal dark grey lenticels, that with age darkens and develops fissures. The bark of the *B. pendula* is a brighter white and shinier than that of *B. pubescens*, and its branches characteristically droop, whereas those of *B. pubescens* grow upwards or horizontally. In addition, *B. pubescens* shoots are covered with a smooth fine down, as opposed to the hairless shoots of *B. pendula*. *B. pendula* leaves are coarsely and unequally double-serrated, larger than those of *B. pubescens* (3-7 cm vs. 2-5 cm), and end in a fine point. *B. pubescens* leaves are egg shaped, with a finely serrated margin and end in a shorter point. Both species are *monoeccious* with male and female inflorescences developing as *unisexual* catkins, wind pollinated. Male catkins develop in summer, shedding pollen the following spring, a few days after female flowers have emerged. Female catkins are smaller, shorter and more erect than the longer, hanging, and clustered, male ones. Female catkins develop into fruits that are 1 to 4 cm long and 6 mm wide cylinder-shaped aggregates that eventually each disperse hundreds of small, winged fruits around August, with the amount varying with tree age and site conditions. In denser stands, birch trees do not flower until they are 20-25 years old but free-standing trees can already flower at the age of ten. While it flowers every year, the production of viable seeds usually peaks every 2-3 years.

### Distribution

*B. pendula* and *B. pubescens* occur naturally throughout most of Europe up to central Siberia. *B. pubescens* has a more northerly and easterly distribution, growing further north in Europe than any other tree species, whereas *B. pendula* can reach southern regions such as the Iberian Peninsula, South Italy and Greece.* Given their wide distribution, these two birches show a high morphological variability and different subspecies and varietals have been described. Moreover, in most parts of Europe they are *sympatric* and can naturally hybridise, generating plants...

Habitat and Ecology

Birch trees commonly live for 90-100 years, and, more rarely, up to 150 years. They are light-demanding, can grow rapidly also on poor soils, their winged fruits are very efficiently distributed by wind and its roots are easily associated with a large number of ectomycorrhizal fungi. These characteristics combine to make birch trees thrive as pioneers during early stages of secondary vegetation succession. They are valuable in the natural or anthropogenic regeneration of woodlands, particularly in the centre of their distribution range. Betula pendula grows best on fairly fertile, light, well-drained soils, particularly when soil conditions are acidic, while Betula pubescens tolerates damper soils and poorly drained heaths. Betula pendula shows a moderate soil-acidifying ability. Birches are most abundant in the boreal zone of northern Europe, where they can co-dominate or dominate in late-successional vegetation. Owing to its cold-hardiness, Betula pubescens also has a higher elevational limit than Betula pendula, often forming the alpine treeline in Nordic countries. Both the northern and elevational distribution limits of Betula pubescens appear to be determined by exposure to cold, dry north-easterly winds in winter, since the species is not particularly wind resistant. Southern distribution limits appear to be set by summer drought, which both species, and particularly Betula pendula, do not tolerate.

Importance and Usage

Birch provides the commercially most important source of hardwood in northern Europe, and is often an important component in conifer plantations, such as those of Scots pine (Pinus sylvestris) and Norway spruce (Picea abies). Birch plantations can also provide a protective habitat for seedlings of other tree species, including those that are more frost-sensitive, such as beech (Fagus sylvatica) and Norway spruce. Because it can tolerate a broad range of site conditions, and poor soils in particular, birch is often used for land reclamation and revegetation, improving the soil so other broad-leaved or coniferous tree species can be planted later. Birches are widely planted in urban areas, roadides and parklands. Some silver birch varieties, such as Betula pendula var. carelica (curly birch), are particularly sought after for veneers and ornamental wood products because they can produce curly grains. Betula pubescens is mainly grown for pulp wood and low-cost fuel wood, as its stems may be too small or poor for use as saw logs or veneers, even if veneer compression may be exploited. In spruce plantations in Scandinavia, naturally growing birch trees increase biodiversity of birds and lichens. Root pressure builds in the lead up to bud burst and causes sap flow early in spring. This birch xylem sap was until recently commonly tapped and consumed in Eastern Europe, either fresh as a tonic, fermented (birch beer or wine), or concentrated into a syrup. Betula pubescens is used as a medicinal and aromatic plant in Croatia. The leaves and bark of Betula pendula are used for their diuretic properties. Ointments for eczema and psoriasis may use birch tar as an astringent ingredient. Birches grow at high altitudes and in European boreal areas. Since mountainous areas in Europe show

Birch provides the commercially most important source of hardwood in northern Europe, and is often an important component in conifer plantations, such as those of Scots pine (Pinus sylvestris) and Norway spruce (Picea abies). Birch plantations can also provide a protective habitat for seedlings of other tree species, including those that are more frost-sensitive, such as beech (Fagus sylvatica) and Norway spruce. Because it can tolerate a broad range of site conditions, and poor soils in particular, birch is often used for land reclamation and revegetation, improving the soil so other broad-leaved or coniferous tree species can be planted later. Birches are widely planted in urban areas, roadides and parklands. Some silver birch varieties, such as Betula pendula var. carelica (curly birch), are particularly sought after for veneers and ornamental wood products because they can produce curly grains. Betula pubescens is mainly grown for pulp wood and low-cost fuel wood, as its stems may be too small or poor for use as saw logs or veneers, even if veneer compression may be exploited. In spruce plantations in Scandinavia, naturally growing birch trees increase biodiversity of birds and lichens. Root pressure builds in the lead up to bud burst and causes sap flow early in spring. This birch xylem sap was until recently commonly tapped and consumed in Eastern Europe, either fresh as a tonic, fermented (birch beer or wine), or concentrated into a syrup. Betula pubescens is used as a medicinal and aromatic plant in Croatia. The leaves and bark of Betula pendula are used for their diuretic properties. Ointments for eczema and psoriasis may use birch tar as an astringent ingredient. Birches grow at high altitudes and in European boreal areas. Since mountainous areas in Europe show
a soil erosion rate higher than the average - especially in the boreal mountain system. Birch species provide a particularly valuable service in watershed protection and soil stabilisation. Both birches are effective in erosion control; furthermore, *Betula pendula* plays a role in soil strength enhancement and is used for vegetated crib walls. The observed colonisation of boreal areas above the treeline by *Betula pendula* and *Betula pubescens* may indicate its further protection potential under climate change.

**Threats and Diseases**

The bronze birch borer (*Agrilus anxius*) constitutes an increasing threat to birch trees. It is a wood-boring beetle native to North America, known to attack all species of birch (with varying susceptibility). Although healthy trees are generally able to produce callus tissue around the *Agrilus* galleries, the European birches have little resistance and if the bronze birch borer were introduced in Europe no natural predators would mitigate its spread. Birch leaves are forage for the larvae of several butterflies, moths and sawfly species. In some cases, such as that of geometrid moth species that feed on the leaves from the outside (e.g. *Epirrita autumnata* and *Operophthera fagata*) in northern Fennoscandia, this can cause pest outbreak conditions with cycles of mass defoliation, followed by collapse of the moth population. Larvae of other insects consume birch tissue from the inside either by burrowing through the leaf tissue, so-called leaf miners, or creating outgrowths, i.e. galls, in leaves, fruits, or fruit scales. Birch trees weakened by leaf miners become more susceptible to secondary invasion by the aforementioned organisms. Fungal diseases can affect all parts of birch trees during all their life stages: birch rust (Melampsoridium betulinum) affects birch leaves, and stunts growth, and reduces life expectancy. *Taphrina betulina* and *Taphrina nana* cause abnormal shoot growth (so-called witch’s broom) and leaf deformations. Yet other fungi, such as birch polycope (*Phellinus betulinus*) causes wood rot, eventually killing infected trees. A range of fungal species are

associated with more general die-back with affects crown health (i.e. Amsborgoria virguliform and Disclosa betulina)\textsuperscript{22-24}. Although the large pine weevil (Hylobius abietis) is mostly known as one of the most serious pests affecting young coniferous forests in Europe, it is also harmful for Betula pendula which partly consists with the natural niche of the large pine weevil\textsuperscript{22-24}. Herivory by short-snouted weevils (Strophophora melanogaster and Otiorhynchus scaber) is another threat to birch\textsuperscript{26}.
